Generalized Model Predictive Pulse Pattern Control Based on Small-Signal Modelling—Part 1: Algorithm

Tinus Dorfling, Hendrik du Toit Mouton, Member, IEEE, and Tobias Geyer, Fellow, IEEE

Abstract-A model predictive controller based on optimized pulse patterns is proposed that is suitable for higher-order linear systems, such as converters with LC filters. The controller manipulates the switching times an optimized pulse pattern. The switching time modifications are approximated by the strengths of impulses, which are based on a small-signal linearization around the nominal switching instants. With these, the evolution of the state variables over the prediction horizon can be described by a set of linear differential equations. An objective function penalizes the predicted tracking error of the controlled variables, such as the converter currents, filter capacitor voltages, and grid currents, over a prediction horizon. Thanks to the use of impulse strengths, the underlying optimization problem is a convex quadratic program, which can be solved in real time to determine the switching time modifications of the pulse pattern to be applied by the controller.

Index Terms—Optimized pulse patterns, synchronous optimal pulse width modulation, model predictive control

I. INTRODUCTION

Optimized pulse patterns (OPPs) [1] are known for their superior harmonic performance. At low pulse numbers (i.e. at low switching frequency to fundamental frequency ratios), OPPs significantly outperform well-known carriedbased pulse-width modulation as well as state-of-the-art control techniques during steady-state conditions, see [2] and [3, Chapter 13.2]. This makes OPPs particularly beneficial for industrial power electronic systems that operate at low switching frequencies (such as medium-voltage drive systems). Due to the computationally demanding optimization problem underling OPPs, the switching angles of the pulse patterns are calculated offline over a range of modulation indices and pulse numbers; the switching angles are stored in lookup tables. During real-time operation of a converter system, the pulse pattern corresponding to the desired operating conditions is read-out from the lookup tables. It is important to realize that OPPs are (offline-calculated) steady-state switching sequences; the nominal pulse patterns are only optimal during steady-state conditions. During transients, OPPs are suboptimal and lead to a sluggish response; a high-bandwidth closed-loop controller is required to ensure a short response time.

However, designing a controller with a high dynamic performance for an OPP-modulated converter is a difficult task. Although control algorithms exist that address the control of first-order converter systems, the control of higher-order converter systems is a largely unexplored topic.

1

In this paper, a new OPP-based model predictive control method is proposed that achieves good performance during transients as well as during steady-state operation. The method

- is applicable to any linear higher-order converter system with multiple state variables and integer switch positions,
- regulates the system states along their optimal steadystate reference trajectories, and
- achieves fast responses during transients.

This paper is structured as follows. First, a review of existing control methods for OPPs is given in Section II. In Section III, a higher-order converter system is described, and it is shown how the steady-state trajectory of such a system can be determined. Section IV explains how the modifications of a pulse pattern are modelled by using the strengths of impulses. A model predictive controller is then derived in Section V.

The implementation and performance evaluation of the proposed control method are discussed in the second part of this paper [4].

II. REVIEW OF CONTROL METHODS FOR OPPS

Unlike carried-based pulse-width modulation, OPPs lack a fixed-modulation interval and do not have regularly-spaced sampling instants at which the ripple component of certain converter quantities is zero. This implies that both the fundamental component and the ripple of the converter quantities are sampled. This results in classical linear controllers interpreting the ripple, which is a natural characteristic of the OPP, as an error. A linear controller will thus attempt to regulate the ripple to zero, resulting in suboptimal pulse patterns during the steady state. In order to prevent this, the bandwidth of the controller should be low so that it does not react to the ripple; consequently, the controller response becomes sluggish. Linear controllers are thus not a suitable choice for OPP-modulated converter systems that require a short response time.

A. Early Methods

As a first step away from a traditional linear controller for pulse patterns, a current trajectory controller was proposed in 1991 for electrical machines [5]. The method first determines the steady-state (stator) current trajectory that results from the pulse pattern. A deadbeat-type controller regulates the stator current along its steady-state trajectory by modifying the

T. Geyer is with ABB System Drives, Turgi 5300, Switzerland; e-mail: t.geyer@ieee.org

switching instants. In 2007, the method was adapted to control the stator flux instead of the stator current trajectory [6]. The advantage of tracking the stator flux trajectory is that the stator flux is independent of the leakage inductance of a machine. However, both methods require the fundamental component and ripple as separate quantities. Due to the fundamental component not being readily available when a converter is modulated by pulse patterns, a dedicated observer is required [7].

B. Model Predictive Pulse Pattern Control

Recently in 2012, the control problem underlying OPPs was formulated in a model predictive control (MPC) framework [8], giving rise to model predictive pulse pattern control (MP³C) [9]. Arguably, MP³C is the most established OPPbased method, as it is being used by ABB in their main medium-voltage drive system [10].

Consider a three-level converter (with a half dc-link voltage of $\frac{V_d}{2}$) that is modulated by a pulse pattern u and that is connected to the stator of an induction machine. For simplicity, only a single phase is considered (the concept generalizes to all three phases). When neglecting the stator resistance, the stator flux ψ_s of an induction machine is simply the integral of the (input) stator voltage,

$$\psi_s(t) = \psi_{s,0} + \frac{V_d}{2} \int_0^t u(\tau) \, \mathrm{d}\tau,$$
 (1)

where $\psi_{s,0}$ is the stator flux at the initial (sampling) instant. With (1) as the internal dynamic model of the predictive controller, the stator flux is predicted at the *end* of the prediction horizon T_p [that is, $\psi_s(T_p)$ is predicted]. Denote with n_{sw} the number of switching transitions that occur during the prediction horizon T_p . It is fairly straightforward to show that by modifying the *i*th switching transition of a pulse pattern by $\Delta t_i = t_i - t_i^*$, where t_i and t_i^* are the modified and nominal switching times, respectively, that the modification in stator flux at the end of the horizon is

$$\Delta \psi_s(\Delta t_i) = -\frac{V_d}{2} \sum_{i=1}^{n_{\rm sw}} \Delta t_i \Delta u_i, \qquad (2)$$

where $\Delta u_i = u_i - u_{i-1} \in \{-1, 1\}$ is the change in switch position (also known as the so-called switching transitions).

Similar to the early trajectory-based methods, MP³C regulates the stator flux ψ_s along its (optimal) steady-state trajectory ψ_s^* . Since the stator flux is simply the (scaled) integral of the pulse pattern, it is easy to derive the steady-state trajectory. Note that MP³C considers the instantaneous stator flux, and, unlike the earlier methods, does not require the fundamental component and ripple to be separate quantities. Since an OPP is, per definition, optimal at steady-state operating conditions, the control algorithm makes no modifications to the pulse pattern in the steady state (assuming idealized conditions). This results in MP³C having a dynamic response similar to deadbeat-type controllers while having the superior harmonic performance of OPPs in the steady state, see [9] and [3, Chapter 13]. In [11], the MP³C algorithm was extended so that carrierbased pulse-width modulated switching patterns can be generated online when operating at high pulse numbers and at low fundamental frequencies. Another control method, similar to the early trajectory-based methods and MP³C, was proposed in [12].

As observed from (1), the internal dynamic model is an integrator. Examples of such loads are induction machines and grid-connected converters where the resistance can be neglected. However, this simple internal dynamic model is also a limitation of MP³C; it is only applicable to (first-order) integrator systems. When considering higher-order systems, such as converters with LC filters, the internal dynamic model of MP3C cannot capture the resonant behaviour of the converter system. To account for this, MP³C needs to be augmented by an additional damping term in its objective function [13], or an outer damping loop must be added [14]. Whilst these approaches might be effective during steady-state operation, the performance during large transients is rather poor. More specifically, to avoid exciting the filter resonance too strongly, large reference step changes should be filtered by a ramp-limiter, resulting in a sluggish step response. These limitations of MP³C promote the need for a generalized OPPbased MPC scheme that is applicable to higher-order converter systems.

C. Methods for Higher-Order OPP-Modulated Systems

Although there exist control methods to address higherorder OPP-modulated converter systems, these methods do have some characteristics that either make them impractical or limit their performance.

In [15], an MPC control problem is formulated with a continuous-time state-space model. The modifications to the switching instants are determined by solving a nonlinear program. However, sinusoidal references are used instead of the (optimal) steady-state trajectory resulting from the pulse pattern. This implies that the (natural) ripple from the pulse pattern is interpreted as an error and will thus be modified, which during steady-state conditions results in a suboptimal performance. The optimization problem, in its original nonlinear form, requires an optimization method to evaluate the matrix exponential at every iteration and, in addition, also requires a moderate amount of matrix multiplications; this results in a high computational burden. In order to simplify the optimization problem to a quadratic program (QP), the state variables are linearized around the nominal switching instants. However, the linearization requires that the three-phase voltage vectors have a fixed switching sequence. This implies that a switching transition in one phase cannot be shifted beyond a switching transition in another phase, thus imposing a major limitation. In combination with this limitation, the modifications to the switching transitions are also required to be very small due to the limited accuracy of the linearization. This results in very conservative constraints that lead to a sluggish response during transients. Furthermore, at certain operating points, the linearized problem also significantly increases the harmonic distortion (see [15, Fig. 3]).

In [16], the MPC control problem is formulated using a discrete-time state-space model. Relative to the current sampling instant k, the controller predicts the system states at even-indexed switching instants (that is, at k + 2, k + 4, and so forth) and can manipulate the odd-indexed switching instants (that is, at k+1, k+3, and so forth). Note that the prediction instants are, therefore, irregularly spaced. The method introduces a nonlinear transformation of the decision variables (which are the odd-indexed switching instants), transforming the problem from a nonconvex optimization problem into a QP. As with [15], the state references are also sinusoidal and therefore suboptimal. Although the method assumes a fixed switching order, the response time is still modest. However, the method does make an assumption regarding the characteristics of the load: the total energy in the system stays constant during an unforced response (that is, when the input and grid voltage are zero), implying elements that dissipate power have to be ignored in the internal model.

Another generalized OPP-based controller is proposed in [17, Chapter 4]. The MPC problem is formulated in the discrete-time domain at regularly-spaced prediction instants. The core principle of the method is to transform the discretevalued pulse pattern into a real-valued control signal that is easy to modify. This is achieved by averaging the pulse pattern between the discrete-time instants. Once the real-valued signal has been modified by solving a QP, a reverse transformation is required in order to retrieve the modified switching transitions. Unlike the methods in [15] and [16], this method uses the optimal steady-state trajectory that results from the pulse pattern as a reference. However, the method does have some limitations. Switching transitions are not allowed to move out of the sampling interval they are contained in, therefore restricting the degree by which the pulse pattern can be modified. Thus, in order to allow moderate modifications, the sampling interval is required to be relatively long. On the other hand, the averaging step introduces an error in the steady-state pulse pattern, which increases as the sampling interval is increased. This creates conflicting objectives. The reverse transformation itself requires an additional optimization problem to be solved: a linear program. Nonetheless, the method results in a decent response time and holds the most promise when compared to the methods of [15] and [16].

The controller proposed in Chapter V has none of the limitations of the aforementioned control methods, and is a natural generalization of MP³C. Furthermore, the proposed controller is practically viable, as it has been implemented on a low-cost field-programmable gate array (see the second part of this paper [4]) and can execute in real-time; none of the aforementioned methods have been verified to be practically feasible.

III. CONVERTER SYSTEM AND ITS STEADY-STATE TRAJECTORY

The formulation of the control algorithm in Section V is general enough so that any linear time-invariant system that is modulated with OPPs can be considered. This includes single-phase and multi-phase converters, two-level and multilevel converters, inverters and rectifiers, and voltage-source and current-source converters. Such a power converter system with linear elements and integer inputs can be described by the continuous-time state-space representation

$$\frac{\mathrm{d}\boldsymbol{x}(t)}{\mathrm{d}t} = \boldsymbol{F}\boldsymbol{x}(t) + \boldsymbol{G}\boldsymbol{u}_{abc}(t) + \boldsymbol{P}\boldsymbol{v}_g(t), \qquad (3)$$

where $x \in \mathbb{R}^{n_x}$ and $v_g \in \mathbb{R}^{n_v}$ are the state and disturbance vectors, respectively, with $n_x \in \mathbb{N}^+$ and $n_v \in \mathbb{N}_0^+$. Note the it is assumed that the disturbance is known. The input vector $u_{abc} = [u_a \ u_b \ u_c]^{\mathrm{T}} \in \mathbb{Z}^3$ is the three-phase switch position (this can easily be extended to multi-phase systems). Finally, F, G, and P are the state, input and disturbance matrices, which characterize the system.

A. Case Study: Grid-Connected NPC Converter

As case study, consider a three-level three-phase neutralpoint-clamped (NPC) converter that is connected to the grid via an LC filter, as depicted in Fig. 1. The phase voltages are denoted by v_p , where $p \in \{a, b, c\}$ are the three phases. Assume that the dc-link capacitors have an infinite capacitance, and that the neutral point N has no fluctuations, dividing the dc-link voltage V_d evenly across the dc-link capacitors.¹ Each phase leg can synthesize three voltage levels: $-\frac{V_d}{2}$, 0, $\frac{V_d}{2}$. Thus, the output voltage for a particular phase is given by

$$v_p = \frac{V_d}{2}u_p,$$

where $u_p \in \{-1, 0, 1\}$ represents the switch position of the particular phase.

The three-phase grid voltages are assumed to be symmetrical, and its phase voltages are shifted by 120 degrees with respect to each other with a positive phase sequence.

B. State-Space Representation of a Grid-Connected NPC Converter

The three-phase converter current, capacitor voltage, and grid current are defined as $i_{abc} = [i_a \ i_b \ i_c]^{\mathrm{T}}$, $v_{c,abc} = [v_{c,a} \ v_{c,b} \ v_{c,c}]^{\mathrm{T}}$, and $i_{g,abc} = [i_{g,a} \ i_{g,b} \ i_{g,c}]^{\mathrm{T}}$, respectively. These quantities are transformed into the stationary orthogonal reference frame with the Clarke transformation,

$$\boldsymbol{\xi}_{\alpha\beta} = \boldsymbol{K}\boldsymbol{\xi}_{abc},$$

which maps any variable $\boldsymbol{\xi}_{abc} = [\xi_a \ \xi_b \ \xi_c]^{\mathrm{T}}$ in the *abc*-plane to the two-dimensional vector $\boldsymbol{\xi}_{\alpha\beta} = [\xi_\alpha \ \xi_\beta]^{\mathrm{T}}$ in the $\alpha\beta$ -plane via the transformation matrix

$$\mathbf{K} = \frac{2}{3} \begin{bmatrix} 1 & -\frac{1}{2} & -\frac{1}{2} \\ 0 & \frac{\sqrt{3}}{2} & -\frac{\sqrt{3}}{2} \end{bmatrix}.$$

Based on this, the state vector is defined as

$$\boldsymbol{x} = \begin{bmatrix} i_{lpha} & i_{eta} & i_{g,lpha} & i_{g,eta} & v_{c,lpha} & v_{c,eta} \end{bmatrix}^{\mathrm{T}}$$

- T

and the converter system is described in a continuous-time state-space form using (3). The grid voltage is defined in the stationary orthogonal reference frame as

$$\boldsymbol{v}_g(t) = \begin{bmatrix} v_{g,\alpha}(t) \\ v_{g,\beta}(t) \end{bmatrix} = \sqrt{\frac{2}{3}} V_g \begin{bmatrix} \sin(\omega_1 t) \\ -\cos(\omega_1 t) \end{bmatrix}$$

¹To address the balancing of the neutral-point potential, the methods proposed in [18] and [19] can be incorporated in the control algorithm.

Fig. 1: Grid-connected neutral-point-clamped converter with an LC filter. The resistances and inductances of the grid and transformer are lumped together as $R_{gt} = R_g + R_t$ and $L_{gt} = L_g + L_t$, respectively. Note that the resistors represent the equivalent series resistances of the filter inductor and capacitor, as well as the winding resistance of the transformer.

where V_g is the root-mean-square (rms) line-to-line grid voltage, and $\omega_1 = 2\pi f_1$ is the fundamental angular frequency. The state-space matrices are shown in the Appendix A. The grid voltage v_g is treated as a known disturbance. Note that the input u_{abc} is given in the three-phase abc frame, whereas the state vector x and the disturbance vector v_g are given in the stationary orthogonal $\alpha\beta$ reference frame.

C. Steady-State Trajectory of a Converter System Modulated by OPPs

The following method is a modification to the method proposed in [20].

It can be shown from (3) that the steady-state trajectory resulting from the nominal pulse pattern u_{abc}^* at time $t \in [0, T_1]$, where T_1 is the fundamental period, is

$$\boldsymbol{x}^{*}(t) = \boldsymbol{e}^{\boldsymbol{F}t}\boldsymbol{x}_{0}^{*} + \int_{0}^{t} \boldsymbol{e}^{\boldsymbol{F}(t-\tau)}\boldsymbol{G}\boldsymbol{u}_{abc}^{*}(\tau) \, \mathrm{d}\tau \\ + \int_{0}^{t} \boldsymbol{e}^{\boldsymbol{F}(t-\tau)}\boldsymbol{P}\boldsymbol{v}_{g}(\tau) \, \mathrm{d}\tau,$$
(4)

where x_0^* is the initial steady-state value at the start of the fundamental period T_1 . In order to calculate the steady-state trajectory over a fundamental period, the initial steady-state value x_0^* first needs to be calculated. Thanks to linearity, the principle of superposition can be used to calculate the effect of the pulse pattern and grid voltage separately as

$$\boldsymbol{x}^{*}(t) = \boldsymbol{x}^{*}_{\text{OPP}}(t) + \boldsymbol{x}^{*}_{g}(t)$$
(5)

where

$$\boldsymbol{x}_{\text{OPP}}^{*}(t) = \boldsymbol{e}^{\boldsymbol{F}t}\boldsymbol{x}_{\text{OPP},0}^{*} + \int_{0}^{t} \boldsymbol{e}^{\boldsymbol{F}(t-\tau)}\boldsymbol{G}\boldsymbol{u}_{abc}^{*}(\tau) \,\mathrm{d}\tau. \quad (6)$$

For now, the grid is ignored and assumed to be shortcircuited. Consider the (three-phase) nominal pulse pattern in Fig. 2, which has N = 12d switching transitions over the fundamental period T_1 (where d is the pulse number). Denote with t_i^* the (three-phase) nominal switching times, where $i = 0, 1, \ldots, N + 1$. The switching times $t_0^* = 0$ and

Fig. 2: Three-phase nominal pulse pattern u_{abc}^* . The pulse number is d = 3, and there are a total of N = 36 switching transitions across all three phases.

 $t_{N+1}^* = T_1$ are introduced to take the boundaries into account. Due to periodicity, it always holds that

$$\boldsymbol{x}_{\text{OPP}}^*(0) = \boldsymbol{x}_{\text{OPP}}^*(T_1) \tag{7}$$

in steady-state conditions; this fact can be used to calculate $x^*_{OPP,0}$. It is easy to see from (6) that

$$\boldsymbol{x}_{\text{OPP}}^*(0) = \mathbf{I}_{n_x} \boldsymbol{x}_{\text{OPP},0}^*,\tag{8}$$

where \mathbf{I}_{n_x} is the identity matrix of dimensions n_x . To calculate $\boldsymbol{x}^*_{\text{OPP}}(T_1)$, note that the three-phase pulse pattern is constant between switching transitions. This leads to the integral of (6) (with $t = T_1$) becoming

$$\begin{split} \boldsymbol{f} &= \sum_{i=0}^{i=N} \int_{t_i^*}^{t_{i+1}^*} \boldsymbol{e}^{\boldsymbol{F}(T_1 - \tau)} \, \mathrm{d}\tau \, \boldsymbol{G} \boldsymbol{u}_{abc}^*(t_i^*) \\ &= \boldsymbol{F}^{-1} \sum_{i=0}^{i=N} \left((\boldsymbol{e}^{\boldsymbol{F}(T_1 - t_i^*)} - \boldsymbol{e}^{\boldsymbol{F}(T_1 - t_{i+1}^*)}) \boldsymbol{G} \boldsymbol{u}_{abc}^*(t_i^*) \right), \end{split}$$

where F is assumed to be invertible for convenience.² Thus,

²In the case that \mathbf{F} is singular, the structure of the matrix must be exploited to solve the integral. For the singular matrix $\mathbf{F} = \begin{bmatrix} a & 0 \\ 0 & 0 \end{bmatrix}$, for example, the expression $\int_0^t \mathbf{e}^{\mathbf{F}t} dt = \begin{bmatrix} (e^{at} - 1)/a & 0 \\ 0 & t \end{bmatrix}$ can be derived.

Fig. 3: The steady-state trajectory (in pu) of the converter system resulting from the nominal pulse pattern u_{abc}^* (including the grid voltage).

the steady-state value at the end of the fundamental period is

$$\boldsymbol{x}_{\text{OPP}}^*(T_1) = \boldsymbol{e}^{\boldsymbol{F}T_1} \boldsymbol{x}_{\text{OPP},0}^* + \boldsymbol{f}.$$
 (9)

It is easy to show from (7) [after inserting (8) and (9)] that the initial steady-state value resulting from the pulse pattern is

$$\boldsymbol{x}_{\text{OPP},0}^* = (\mathbf{I}_{n_x} - \boldsymbol{e}^{\boldsymbol{F}T_1})^{-1} \boldsymbol{f}, \qquad (10)$$

where $x_{OPP,0}$ is assumed to be unique in the steady state.³

With the initial steady-state value $x_{OPP,0}^*$ known, the steady-state trajectory x_{OPP}^* resulting from the pulse pattern can be calculated over the fundamental period using (6). Typically, the steady-state trajectory x^* is required at discrete sampling instants of T_s (the sampling interval of the controller).

Now, consider the grid voltage. The steady-state trajectory resulting from the grid voltage can be described as

$$\boldsymbol{x}_{g}^{*}(t) = \boldsymbol{e}^{\boldsymbol{F}t}\boldsymbol{x}_{g,0}^{*} + \int_{0}^{t} \boldsymbol{e}^{\boldsymbol{F}(t-\tau)}\boldsymbol{P}\boldsymbol{v}_{g}(\tau) \, \mathrm{d}\tau,$$

where the integral is not trivial to solve since the grid voltage is sinusoidal. Fortunately, the effect of the grid can be calculated using well-known phasor analysis; all the converter states resulting from the grid voltage only consist of a fundamental component. After calculating the effect of the grid voltage over the fundamental period, the steady-state trajectory resulting from the grid voltage can be added to that of the pulse pattern as shown with (5). Alternatively, the effect of the grid voltage can be considered by representing the grid voltage as a harmonic resonator and including it as additional state variables. Fig. 3 shows an example of a steady-state trajectory x^* in the *abc* reference frame. The parameters of the system can be found in [4, Appendix C]. The pulse number is d = 5and the system is operating at rated conditions with unity power factor.

IV. SMALL-SIGNAL MODELLING OF MODIFICATIONS OF A PULSE PATTERN

This section explains how the modifications of a pulse pattern are modelled.

A. Overview of Small-Signal Modelling

Although no clear definition of *small-signal modelling* could be found in the literature, the term, usually, refers to a linearization of a nonlinear system around an operating point [21, Section 3.10]. Note that small-signal modelling does not strictly imply a linearization around a single operating point; the system can also be linearized around a trajectory (which is the case in this paper).

There are three types of variables associated with smallsignal modelling. The first is the *complete-signal variables*

$$\xi(t) = \xi^*(t) + \tilde{\xi}(t),$$
 (11)

³This is true for most plants. However, for plants where the resistive components are not taken into account (such as an integrator or resonator), there is no unique trajectory since e^{Ft} will not diminish as $t \to \infty$. If no unique trajectory exists, then some components of $x^*_{OPP,0}$ must be treated as free variables.

Fig. 4: Using impulses to represent rectangular pulses (that is, modifications to a pulse pattern).

which is the sum of the *large-signal variables* ξ^* and *small-signal variables* $\tilde{\xi}$. The large-signal variables represent the trajectory that the system is linearized around. The small-signal quantities $\tilde{\xi}$ represent the linearized variables, which are perturbations superimposed on the large-signal variables. In this paper, the large-signal variables are the steady-state variables (the nominal pulse pattern and its resulting steady-state trajectory), which are interpreted as references. The complete-signal variables represent the actual (measured) values of the system. From (11), the small-signal variables can be expressed as

$$\hat{\xi}(t) = \xi(t) - \xi^*(t),$$
 (12)

which is interpreted as an error (specifically, small-signal state variables represent errors). A controller can be used to modify the small-signal input in order to drive the small-signal state variables to zero. In steady-state conditions, all small-signal variables are zero (assuming idealized conditions).

B. Linear Approximation to Modifications of a Pulse Pattern

For the moment, only single-phase pulse patterns are considered for convenience. Before continuing, two types of pulse patterns are introduced. The first is the reference pulse pattern, denoted with u^* , and is referred to as the *nominal pulse pattern*. The nominal pulse pattern has *n* switching transitions that occur at the *nominal* switching instants $t_i^*, i = 1, ..., n$, and can be represented as

$$u^{*}(t) = u_{0} + \sum_{i=1}^{n} \Delta u_{i} h(t - t_{i}^{*}), \qquad (13)$$

where h is the Heavyside (unit) step function and u_0 is the initial (nominal) switch position. The direction of a switching transition is denoted by $\Delta u_i = u_i - u_{i-1}$, where $u_{i-1}, u_i \in \mathbb{Z}$. The nominal pulse pattern is the offline-calculated pulse pattern.

The second pulse pattern is called the *modified pulse pattern*, and it is denoted with u. The modified pulse pattern has modified switching transitions that occur at the *modified* switching instants

$$t_i = t_i^* + \Delta t_i,$$

where Δt_i is the time modification. The modified pulse pattern can be represented as

$$u(t) = u_0 + \sum_{i=1}^{n} \Delta u_i h(t - (t_i^* + \Delta t_i)).$$
(14)

It can be observed in Fig. 4 that the *i*th switching time modification is associated with an area of

$$\lambda_i = -\Delta t_i \Delta u_i \tag{15}$$

that is removed or added to the nominal pulse pattern.

Recall that the time derivative of the step function h is the Dirac delta function, or simply the impulse, δ . By using a first-order Taylor series expansion of the step functions around the nominal switching times t_i^* , (14) can be approximated by

$$u(t) \approx u_0 + \sum_{i=1}^n \Delta u_i \left(h(t - t_i^*) - \Delta t_i \delta(t - t_i^*) \right),$$

which can be written as⁴

$$u(t) = u_0 + \sum_{i=1}^{n} \Delta u_i h(t - t_i^*) + \sum_{i=1}^{n} \lambda_i \delta(t - t_i^*)$$
(16)

with the definition of (15). The (linearized) modified pulse pattern in (16) consists of two terms. The first one is the nominal pulse pattern, whereas the second expression states the (approximated) modifications. These modifications are impulses placed at the nominal switching time instants t_i^* with strengths λ_i .

According to the definition of small-signal variables in (12), the *small-signal input* is defined as

$$\tilde{u}(t) = u(t) - u^{*}(t) = \sum_{i=1}^{n} \lambda_{i} \delta(t - t_{i}^{*}).$$
(17)

By rewriting (15), the impulse strengths can be translated into the switching time modifications as

$$\Delta t_i = -\frac{\lambda_i}{\Delta u_i}.\tag{18}$$

Note that the translation from impulse strengths to switching time modification is based on the linearization in (16). More specifically, the areas of the (shaded) rectangular pulses in Fig. 4 are *approximated* by the strengths of the impulses; the narrower the rectangular pulses, the better the approximation.

C. The Three-Phase Case

This section generalizes the notation and techniques developed in the previous section to the three-phase case. The modification of the *i*th switching instant of phase $p \in \{a, b, c\}$ is

$$\Delta t_{p,i} = t_{p,i} - t_{p,i}^*, \tag{19}$$

where $t_{p,i}$ and $t_{p,i}^*$ are the modified and nominal switching instants, respectively. The (direction of the) *i*th switching transition in a particular phase is

$$\Delta u_{p,i} = u_{p,i} - u_{p,i-1} \tag{20}$$

where $u_{p,i}, u_{p,i-1} \in \{-1, 0, 1\}$. Generalizing (15), the *i*th impulse strength in phase p is

$$\lambda_{p,i} = -\Delta t_{p,i} \Delta u_{p,i}.$$
(21)

Fig. 5: Three-phase pulse pattern.

Consider the modified three-phase pulse pattern u_{abc} over the time interval $t \in [0, T_p]$, where T_p is the *prediction horizon* of a predictive controller. Following the principle derived in (16), define the modified pulse pattern as the superposition

$$\boldsymbol{u}_{abc}(t,\lambda_{p,i}) = \boldsymbol{u}_{abc}^{*}(t) + \tilde{\boldsymbol{u}}_{abc}(t,\lambda_{p,i})$$
(22)

of the three-phase nominal pulse pattern

$$\boldsymbol{u}_{abc}^{*}(t) = \begin{bmatrix} u_{a}(t) \\ u_{b}(t) \\ u_{c}(t) \end{bmatrix} = \begin{bmatrix} u_{a,0} + \sum_{i=1}^{n_{a}} \Delta u_{a,i}h(t - t_{a,i}^{*}) \\ u_{b,0} + \sum_{i=1}^{n_{b}} \Delta u_{b,i}h(t - t_{b,i}^{*}) \\ u_{c,0} + \sum_{i=1}^{n_{c}} \Delta u_{c,i}h(t - t_{c,i}^{*}) \end{bmatrix}$$
(23)

and the three-phase small-signal input

$$\tilde{\boldsymbol{u}}_{abc}(t,\lambda_{p,i}) = \begin{bmatrix} \tilde{u}_a(t,\lambda_{a,i})\\ \tilde{u}_b(t,\lambda_{b,i})\\ \tilde{u}_c(t,\lambda_{c,i}) \end{bmatrix} = \begin{bmatrix} \sum_{i=1}^{n_a} \delta(t-t^*_{a,i})\lambda_{a,i}\\ \sum_{i=1}^{n_b} \delta(t-t^*_{b,i})\lambda_{b,i}\\ \sum_{i=1}^{n_c} \delta(t-t^*_{c,i})\lambda_{c,i} \end{bmatrix}.$$
(24)

In here, n_p is introduced as the number of switching transitions in phase p that fall within the horizon T_p , and $\lambda_{p,i}$ as the strength of the *i*th impulse in that phase. Note that the nominal switching times $t_{p,i}^*$ are defined relative to the current time step $t_0 = 0$. The total number of switching transitions in the three phases within the horizon T_p is denoted by $n_{sw} = n_a + n_b + n_c$. In Fig. 5, for example, there are $n_{sw} = 9$ switching transitions $(n_a = 2, n_b = 4, \text{ and } n_c = 3)$.

V. THE SMALL-SIGNAL CONTROLLER

This section introduces the generalized model predictive pulse pattern controller, which is referred to as the *small-signal controller*. In a first step, as with any model predictive controller, an internal dynamic model is first derived.

A. Internal Dynamic Model

Recall the differential equation of the power converter system in (3). By integrating (3), and with the modified pulse pattern u_{abc} as the input, the future state vector at time $t \in [0, T_p]$ is

$$\boldsymbol{x}(t,\lambda_{p,i}) = \boldsymbol{e}^{\boldsymbol{F}t}\boldsymbol{x}_0 + \int_0^t \boldsymbol{e}^{\boldsymbol{F}(t-\tau)}\boldsymbol{G}\boldsymbol{u}_{abc}(\tau,\lambda_{p,i}) d\tau + \int_0^t \boldsymbol{e}^{\boldsymbol{F}(t-\tau)}\boldsymbol{P}\boldsymbol{v}_g(\tau) d\tau,$$
(25)

 4 For convenience, the approximation is replaced with an equality in the sequel.

where x_0 is the initial state at time $t_0 = 0$. Similarly, as shown in Section III-C, the (optimal) steady-state trajectory follows from the nominal pulse pattern over the prediction horizon T_p as

$$\boldsymbol{x}^{*}(t) = \boldsymbol{e}^{\boldsymbol{F}t}\boldsymbol{x}_{0}^{*} + \int_{0}^{t} \boldsymbol{e}^{\boldsymbol{F}(t-\tau)}\boldsymbol{G}\boldsymbol{u}_{abc}^{*}(\tau) d\tau + \int_{0}^{t} \boldsymbol{e}^{\boldsymbol{F}(t-\tau)}\boldsymbol{P}\boldsymbol{v}_{g}(\tau) d\tau,$$
(26)

where x_0^* is the initial optimal state.⁵

According to (12), the small-signal state vector is defined as

$$\tilde{\boldsymbol{x}}(t,\lambda_{p,i}) = \boldsymbol{x}(t,\lambda_{p,i}) - \boldsymbol{x}^*(t)$$
(27)

which is referred to as the *small-signal error*; this term is used to emphasize that the small-signal state vector represents an error. By inserting (26) and (25) with (22) into (27), the small-signal error follows as

$$\tilde{\boldsymbol{x}}(t,\lambda_{p,i}) = \boldsymbol{e}^{\boldsymbol{F}t}\tilde{\boldsymbol{x}}_0 + \int_0^t \boldsymbol{e}^{\boldsymbol{F}(t-\tau)}\boldsymbol{G}\tilde{\boldsymbol{u}}_{abc}(\tau,\lambda_{p,i}) \ d\tau, \quad (28)$$

where $\tilde{x}_0 = x_0 - x_0^*$ is the initial small-signal error. It can be observed that the grid is not part of the small-signal model. However, the grid voltage is required when selecting the appropriate pulse pattern according to the operating conditions.

In the case of $\mathbf{F} = \mathbf{0}_{n_x \times n_x}$ (i.e. the system is a pure integrator) and $t = T_p$, it can easily be verified that the internal dynamic model of (28) reduces to that of MP³C in (1). In other words, the proposed controller is a generalization of MP³C to higher-order systems.

B. Compact Vector Form of the Small-Signal Error

The small-signal error (28) can be written in a compact form. First, the small-signal input \tilde{u}_{abc} [see (24)] is decomposed into each phase, resulting in (28) becoming

$$\tilde{\boldsymbol{x}}(t,\lambda_{p,i}) = \boldsymbol{e}^{\boldsymbol{F}t}\tilde{\boldsymbol{x}}_{0} + \int_{0}^{t} \boldsymbol{e}^{\boldsymbol{F}(t-\tau)} \left(\boldsymbol{G}_{a} \sum_{i=1}^{n_{a}} \delta(\tau - t_{a,i}^{*}) \lambda_{a,i} + \boldsymbol{G}_{b} \sum_{i=1}^{n_{b}} \delta(\tau - t_{b,i}^{*}) \lambda_{b,i} + \boldsymbol{G}_{c} \sum_{i=1}^{n_{c}} \delta(\tau - t_{c,i}^{*}) \lambda_{c,i} \right) d\tau,$$
(29)

where $G_a = G[1 \ 0 \ 0]^T$, $G_b = G[0 \ 1 \ 0]^T$, and $G_c = G[0 \ 0 \ 1]^T$. By using the well-known sifting property of the impulse,

$$\int_{-\infty}^{t} f(\tau) \delta(\tau - t_{p,i}^{*}) \ d\tau = f(t_{p,i}^{*}) h(t - t_{p,i}^{*}),$$

and using basic algebraic manipulations, (29) becomes

$$\tilde{\boldsymbol{x}}(t,\boldsymbol{\Lambda}) = \boldsymbol{e}^{\boldsymbol{F}t}\tilde{\boldsymbol{x}}_0 + \boldsymbol{\Phi}(t)\boldsymbol{\Lambda},\tag{30}$$

⁵Note that \boldsymbol{x}_0^* of (26) refers to the initial state at the current time instant, whereas \boldsymbol{x}_0^* of (4) refers to the initial state at the start of the fundamental period.

where $\mathbf{\Phi} \in \mathbb{R}^{n_x \times n_{sw}}$ is the input matrix,

$$\begin{aligned} \Phi(t) &= \\ \left[e^{F(t-t_{a,1}^{*})} G_{a}h(t-t_{a,1}^{*}) \cdots e^{F(t-t_{a,n_{a}}^{*})} G_{a}h(t-t_{a,n_{a}}^{*}) \right. \\ \left. e^{F(t-t_{b,1}^{*})} G_{b}h(t-t_{b,1}^{*}) \cdots e^{F(t-t_{b,n_{b}}^{*})} G_{b}h(t-t_{b,n_{b}}^{*}) \right. \\ \left. e^{F(t-t_{c,1}^{*})} G_{c}h(t-t_{c,1}^{*}) \cdots e^{F(t-t_{c,n_{c}}^{*})} G_{c}h(t-t_{c,n_{c}}^{*}) \right], \end{aligned}$$

$$(31)$$

and $\mathbf{\Lambda} \in \mathbb{R}^{n_{sw}}$ is introduced as the *strength vector*,

$$\mathbf{\Lambda} = [\lambda_{a,1} \cdots \lambda_{a,n_a} \lambda_{b,1} \cdots \lambda_{b,n_b} \lambda_{c,1} \cdots \lambda_{c,n_c}]^{\mathrm{T}}, \quad (32)$$

with the n_{sw} impulse strengths over the horizon T_p . As an example, the strength vector corresponding to Fig. 5 is $\mathbf{\Lambda} = [\lambda_{a,1} \ \lambda_{a,2} \ \lambda_{b,1} \ \lambda_{b,2} \ \lambda_{b,3} \ \lambda_{b,4} \ \lambda_{c,1} \ \lambda_{c,2} \ \lambda_{c,3}]^{\mathrm{T}}$.

C. Objective Function

The control objectives are to minimize the small-signal error (which relates to the tracking error) across the prediction horizon and to penalize modifications to the nominal pulse pattern (which relates to the control effort). These control objectives can be mapped into a quadratic objective function as^6

$$J(\mathbf{\Lambda}) = \int_0^{T_p} \frac{1}{2} \|\tilde{\boldsymbol{x}}(t, \mathbf{\Lambda})\|_{\boldsymbol{Q}}^2 dt + \frac{1}{2} \|\mathbf{\Lambda}\|_{\boldsymbol{R}}^2.$$
(33)

The first term penalizes with the positive (semi)definite diagonal (penalty) matrix $Q \in \mathbb{R}^{n_x \times n_x}$ the integral of the small-signal error over the prediction horizon T_p . The diagonal (penalty) matrix $R \in \mathbb{R}^{n_{sw} \times n_{sw}}$ corresponding to the penalty on the switching modifications is also required to be positive (semi)definite. The penalty on the control effort inhibits the controller being overly aggressive. This is useful when modelling errors (recall that modifications to a pulse pattern are approximated and not exact) and noise (from measurement devices and observers) are present in a system.

The objective function can be written as the quadratic function

$$J(\mathbf{\Lambda}) = \frac{1}{2}\mathbf{\Lambda}^{\mathrm{T}} \boldsymbol{H} \boldsymbol{\Lambda} + \boldsymbol{c}^{\mathrm{T}} \boldsymbol{\Lambda}, \qquad (34)$$

where $\boldsymbol{H} \in \mathbb{R}^{n_{sw} \times n_{sw}}$ is known as the *Hessian* and contains the second-order partial derivatives of *J*, and $\boldsymbol{c} \in \mathbb{R}^{n_{sw}}$ is a vector with linear coefficients. The derivation of (34) can be found in the Appendix B.

D. Constraints

Constraints are required on the switching time modifications to ensure a feasible pulse pattern. Specifically, the modified switching transitions of each phase are required to be in ascending order, nonnegative, and not moved beyond the prediction horizon, that is,

$$0 \le t_{p,1} \le t_{p,2} \le \ldots \le t_{p,n_p} \le T_p$$
 (35)

for all $p \in \{a, b, c\}$. Alternatively, the n_p th switching transition in a phase can be upper bounded by the next nominal switching

transition beyond the horizon, t_{p,n_p+1}^* . Since the impulse strengths $\lambda_{p,i}$ are the decision variables, the set of constraints (35) can be recast in terms of the impulse strengths $\lambda_{p,i}$ with the help of (19) and (21) as

$$0 \le t_{p,1}^* - \frac{\lambda_{p,1}}{\Delta u_{p,1}} \le t_{p,2}^* - \frac{\lambda_{p,2}}{\Delta u_{p,2}} \le \dots \le t_{p,n_p}^* - \frac{\lambda_{p,n_p}}{\Delta u_{p,n_p}} \le T_p$$
(36)

Applying (36) to the phases a, b, and c, the constraint

$$A\Lambda \le b \tag{37}$$

in matrix form arises, with $\boldsymbol{A} = \text{blockdiag}(\boldsymbol{A}_a, \boldsymbol{A}_b, \boldsymbol{A}_c) \in \mathbb{R}^{(n_{\text{sw}}+3) \times n_{\text{sw}}}$ and $\boldsymbol{b} = [\boldsymbol{b}_a^{\text{T}} \ \boldsymbol{b}_b^{\text{T}} \ \boldsymbol{b}_c^{\text{T}}]^{\text{T}} \in \mathbb{R}^{n_{\text{sw}}+3}$, where \boldsymbol{A}_p and \boldsymbol{b}_p are defined in the Appendix C.

E. Quadratic Program

Minimizing the objective function (34) while respecting the constraint (37) leads to the quadratic program (QP)

$$\boldsymbol{\Lambda}_{\rm opt} = \arg\min_{\boldsymbol{\Lambda}} \quad \frac{1}{2} \boldsymbol{\Lambda}^{\rm T} \boldsymbol{H} \boldsymbol{\Lambda} + \boldsymbol{c}^{\rm T} \boldsymbol{\Lambda} \tag{38a}$$

subject to
$$A\Lambda \leq b$$
. (38b)

The strength vector Λ in (32) is the decision (or optimization) variable, and Λ_{opt} is the optimal solution to the QP. The latter cannot be computed algebraically; instead, numerical optimization techniques must be employed, such as gradient methods, active-set methods, or interior point methods.

Note that the problem (38) is convex, since the constraints are linear and the objective function is quadratic in the decision variable with a positive (semi)definite Hessian H. This can be shown from the fact that penalty matrices Q and R are positive (semi)definite.

F. Optimal Switching Instants

Having solved the QP (38), the vector of optimal impulse strengths $\Lambda_{\rm opt}$ is translated with (21) into the optimal switching instant modifications

$$\Delta t_{\text{opt},p,i} = -\frac{\lambda_{\text{opt},p,i}}{\Delta u_{p,i}}.$$
(39)

By adding these modifications to the nominal switching instants of the pulse pattern, the optimal switching instants are obtained as

$$t_{\text{opt},p,i} = t_{p,i}^* - \frac{\lambda_{\text{opt},p,i}}{\Delta u_{p,i}},\tag{40}$$

where (19) has been rewritten.

G. Receding Horizon Policy

The controller operates at discrete-time steps kT_s , where $k \in \mathbb{N}$, and T_s is the sampling interval. Note that, even though the controller operates at discrete-time instants kT_s , the switching instant modification is formulated in the continuous-time domain. This implies that the modified switching instants are real-valued quantities.

Out of the long prediction horizon, only the modified switching instants within the current sampling interval are applied, that is, between kT_s and $(k + 1)T_s$. Then, at each

 $^{^6 {\}rm The}$ scaling factor of $\frac{1}{2}$ is added to ensure the problem can be written in standard quadratic form.

(b) The prediction horizon at the second sampling instant.

Fig. 6: The receding horizon policy.

Fig. 7: Block diagram with the small-signal controller.

subsequent sampling instant, the modified switching instants from the previous sampling instant are discarded and the nominal switching instants are re-optimized based on new information. This process, illustrated in Fig. 6, is known as the *receding horizon* policy [22, Section 1.1], which provides feedback and makes the controller robust to disturbances and modelling errors.

H. Summary

The overall control diagram, with the small-signal controller included, is shown in Fig. 7. The control algorithm consists of the following steps:

- 1) The real power P^* and reactive power Q^* references are mapped into a modulation index m_a and pulse pattern phase ϕ , which depends on the grid voltage v_g , in the *Converter Reference* block via simple phasor analysis.
- 2) For the given modulation index m_a and the selected pulse number d, the nominal pulse pattern is read-out from a lookup table and phase-shifted accordingly by ϕ in the *OPP Selector* block.
- 3) The optimal state reference trajectory x^* is generated over a fundamental period in the block *Reference Generator*, as explained in Section III-C.
- 4) At a given sampling instant, the Reference Generator

supplies the initial (reference) state x_0^* .

- 5) The small-signal controller first calculates the initial small-signal error, $\tilde{x}_0 = x_0 x_0^*$. Then, in the block *Construct QP*, it builds the Hessian *H* according to (45) and the coefficient vector *c* according to (48) in Appendix B.
- 6) By solving the QP (38) in the *Solve QP* block, the vector of optimal impulse strengths Λ_{opt} is found. The strengths $\lambda_{p,i}$ are translated back to the transition advancements and delays $\Delta t_{opt,p,i}$, which are then added to the nominal switching times $t_{p,i}^*$ of the pulse pattern to yield the optimal (modified) switching instants $t_{opt,p,i}$, in accordance with (40).
- 7) The switching transitions within the sampling interval are applied by the *Gating Scheduler* block.

Note that Steps 1 to 3 are only required if the operating point changes.

VI. CONCLUSIONS

The original MP³C concept in [9] was devised for first-order systems, such as the stator winding of an electrical machine. This paper generalized MP³C to make it applicable to higherorder systems, such as grid-connected converters with an LCfilter. The switching instant modifications of the pulse pattern are modified by the controller to regulate the state vector along its optimal trajectory. Assuming that these corrections occur instantaneously at the nominal switching instants allows one to model the corrections as strengths of impulses. This simplification ensures that the state dynamics are linear in the controller corrections; the resulting optimization problem underlying the model predictive controller is, thus, a QP.

The second part of this paper will show how the control algorithm can be implemented on a low-cost field-programmable gate array and how it is able to execute in real-time within a short sampling interval [4].

APPENDIX A STATE-SPACE MATRICES

The state-space matrices of the case study are

$$\boldsymbol{F} = \begin{bmatrix} -\frac{R+R_C}{L}\mathbf{I}_2 & \frac{R_C}{L}\mathbf{I}_2 & -\frac{1}{L}\mathbf{I}_2 \\ \frac{R_C}{L_{gt}}\mathbf{I}_2 & -\frac{R_{gt}+R_C}{L_{gt}}\mathbf{I}_2 & \frac{1}{L_{gt}}\mathbf{I}_2 \\ \frac{1}{C}\mathbf{I}_2 & -\frac{1}{C}\mathbf{I}_2 & \mathbf{0}_{2\times2} \end{bmatrix},$$

$$\boldsymbol{G} = \frac{V_d}{2L} \begin{bmatrix} \mathbf{I}_2 \\ \mathbf{0}_{2\times2} \\ \mathbf{0}_{2\times2} \end{bmatrix} \boldsymbol{K}, \text{ and } \boldsymbol{P} = \frac{1}{L_{gt}} \begin{bmatrix} \mathbf{0}_{2\times2} \\ -\mathbf{I}_2 \\ \mathbf{0}_{2\times2} \end{bmatrix}.$$

In here, I_2 denotes the identity matrix with dimensions two, and $0_{2\times 2}$ is a 2×2 zero matrix.

APPENDIX B

DERIVATION OF THE QUADRATIC FORM

Consider the two terms of the objective function, see (33). The first term can be expanded to

$$\begin{split} H_{1}(\mathbf{\Lambda}) &= \frac{1}{2} \int_{0}^{T_{p}} \left(\boldsymbol{e}^{Ft} \tilde{\boldsymbol{x}}_{0} + \boldsymbol{\Phi}(t) \mathbf{\Lambda} \right)^{\mathrm{T}} \boldsymbol{Q} \left(\boldsymbol{e}^{Ft} \tilde{\boldsymbol{x}}_{0} + \boldsymbol{\Phi}(t) \mathbf{\Lambda} \right) dt, \\ &= \frac{1}{2} \int_{0}^{T_{p}} \left(\mathbf{\Lambda}^{\mathrm{T}} \boldsymbol{\Upsilon}(t) \mathbf{\Lambda} + \boldsymbol{\Theta}^{\mathrm{T}}(t) \mathbf{\Lambda} \right) dt + \boldsymbol{\theta}, \\ &= \frac{1}{2} \mathbf{\Lambda}^{\mathrm{T}} \left(\underbrace{\int_{0}^{T_{p}} \boldsymbol{\Upsilon}(t) dt}_{V} \right) \mathbf{\Lambda} + \left(\underbrace{\int_{0}^{T_{p}} \boldsymbol{\Theta}^{\mathrm{T}}(t) dt}_{c} \right) \mathbf{\Lambda} + \boldsymbol{\theta}, \end{split}$$
(41)

m

where

and

$$\Upsilon(t) = \Phi^{-}(t)Q\Phi(t), \qquad (42)$$

$$\boldsymbol{\Theta}^{\mathrm{T}}(t) = (\boldsymbol{e}^{\boldsymbol{F}t} \tilde{\boldsymbol{x}}_0)^{\mathrm{T}} \boldsymbol{Q} \boldsymbol{\Phi}(t), \qquad (43)$$

$$\theta = \frac{1}{2} \int_0^{T_p} (\boldsymbol{e}^{\boldsymbol{F}t} \tilde{\boldsymbol{x}}_0)^{\mathrm{T}} \boldsymbol{Q} (\boldsymbol{e}^{\boldsymbol{F}t} \tilde{\boldsymbol{x}}_0) \, dt.$$
(44)

Consider the (i', j')th entry of the $n_{sw} \times n_{sw}$ matrix V [i.e. the integral of (42)]. Assume that the *i*'th entry corresponds to phase $p_1 \in \{a, b, c\}$ and the *i*th switching transition in that phase. Using Fig. 5 as an example, i' = 5 refers to $p_1 = b$ and i = 3. The quantities p_2 and j are defined accordingly for a given j'. Following some algebraic manipulations, it can be shown that the (i', j')th entry of V is

$$\boldsymbol{V}_{(i',j')} = \boldsymbol{G}_{p_1}^{\mathrm{T}} \boldsymbol{e}^{\boldsymbol{F}^{\mathrm{T}}(t_{ij}^* - t_{p_1,i}^*)} \boldsymbol{\Xi}(T_p - t_{ij}^*) \; \boldsymbol{e}^{\boldsymbol{F}(t_{ij}^* - t_{p_2,j}^*)} \boldsymbol{G}_{p_2},$$
(45)

where $t_{ij}^* = \max\{t_{p_1,i}^*, t_{p_2,j}^*\}$, and

$$\boldsymbol{\Xi}(\Delta t) = \int_0^{\Delta t} \boldsymbol{e}^{\boldsymbol{F}^{\mathrm{T}}\tau} \boldsymbol{Q} \boldsymbol{e}^{\boldsymbol{F}\tau} \, d\tau.$$
 (46)

Calculating the integral of the product of two matrix exponentials, which do not commute, is not trivial. Recall the following theorem from [23]: The integral of (46) can be calculated as

$$\boldsymbol{\Xi}(\Delta t) = \boldsymbol{M}^{\mathrm{T}}(\Delta t) \boldsymbol{N}(\Delta t), \qquad (47)$$

where

$$e \begin{bmatrix} -F^{\mathrm{T}} & Q \\ \mathbf{0}_{n_{x} \times n_{x}} & F \end{bmatrix}^{\Delta t} = \\ \begin{bmatrix} e^{-F^{\mathrm{T}} \Delta t} & \overbrace{e^{-F^{\mathrm{T}} \Delta t} \int_{0}^{\Delta t} e^{F^{\mathrm{T}} \tau} Q e^{F \tau} d\tau} \\ \mathbf{0}_{n_{x} \times n_{x}} & \underbrace{e^{F \Delta t}}_{M(\Delta t)} \end{bmatrix}.$$

Following similar derivations, it can be shown that i'th entry of the n_{sw} -dimensional column vector c [i.e. the integral of (43)] is

$$\boldsymbol{c}_{i'}^{\mathrm{T}} = \tilde{\boldsymbol{x}}_{0}^{\mathrm{T}} \boldsymbol{e}^{\boldsymbol{F}^{\mathrm{T}} \boldsymbol{t}_{p,i}^{*}} \boldsymbol{\Xi}(T_{p} - \boldsymbol{t}_{p,i}^{*}) \boldsymbol{G}_{p}.$$
(48)

Note that θ in (41) is not a function of the strength vector Λ . Therefore, it is merely a constant in the objective

The first term of the objective function, J_1 , which minimizes the small-signal error, can now be written as

$$J_1(\mathbf{\Lambda}) = \frac{1}{2} \mathbf{\Lambda}^{\mathrm{T}} \mathbf{V} \mathbf{\Lambda} + \mathbf{c}^{\mathrm{T}} \mathbf{\Lambda}.$$
 (49)

The second term of the objective function (33), which penalises the entries of the strength vector Λ , is simply

$$J_2(\mathbf{\Lambda}) = \frac{1}{2} \mathbf{\Lambda}^{\mathrm{T}} \mathbf{R} \mathbf{\Lambda}.$$
 (50)

The objective function can now be written in its standard quadratic form as

$$J(\mathbf{\Lambda}) = J_1(\mathbf{\Lambda}) + J_2(\mathbf{\Lambda}) = \frac{1}{2} \mathbf{\Lambda}^{\mathrm{T}} (\mathbf{V} + \mathbf{R}) \mathbf{\Lambda} + \mathbf{c}^{\mathrm{T}} \mathbf{\Lambda}$$
$$= \frac{1}{2} \mathbf{\Lambda}^{\mathrm{T}} \mathbf{H} \mathbf{\Lambda} + \mathbf{c}^{\mathrm{T}} \mathbf{\Lambda}.$$
(51)

APPENDIX C Matrix Form of Constraints

The matrix $A_p \in \mathbb{R}^{(n_p+1) \times n_p}$ and vector $b_p \in \mathbb{R}^{n_p+1}$ are defined as

$$\boldsymbol{A}_{p} = \begin{bmatrix} \frac{1}{\Delta u_{p,1}} & 0 & 0 & \cdots & 0 & 0\\ -\frac{1}{\Delta u_{p,1}} & \frac{1}{\Delta u_{p,2}} & 0 & \cdots & 0 & 0\\ 0 & -\frac{1}{\Delta u_{p,2}} & \frac{1}{\Delta u_{p,3}} & \cdots & 0 & 0\\ \vdots & & \ddots & \vdots & \vdots\\ 0 & 0 & 0 & \cdots & -\frac{1}{\Delta u_{p,np-1}} & \frac{1}{\Delta u_{p,np}}\\ 0 & 0 & 0 & \cdots & 0 & \frac{1}{\Delta u_{p,np}} \end{bmatrix}$$

and

$$\boldsymbol{b}_p = \begin{bmatrix} t_{p,1}^* & t_{p,2}^* - t_{p,1}^* & \cdots & T_p - t_{p,n_p}^* \end{bmatrix}^{\mathrm{T}},$$

respectively.
